Traditional agricultural practices enable sustainable remediation of highly polluted soils in Southern Spain for cultivation of food crops.

Abstract

This study relates elemental content of a range of edible crops grown in soils severely polluted by metals and metalloids as affected by traditional smallholder management practices. Five agricultural plots close to a sulfidic waste dump were monitored. Soil analysis demonstrated elevated concentrations of As, Cu, Pb and Zn that were greatly in excess of maximum statutory limits for agricultural soils in this region. The main vegetables (lettuce, chard, onion, potatoes) and lemon, together with their associated soils, were measured for elemental content. Extractable soil element concentrations were very low. There were differences in elemental accumulation between crops, but none exceeded statutory concentrations in edible parts. Soil-plant transfer factors were uniformly low for all elements and crops. It is concluded that traditional soil management practices (annual liming and application of animal manures) have created conditions for sustainable long-term safety use, with potential for multiple end-use, of these highly polluted soils

Keywords: Trace elements, edible plants, soil pollution, Tharsis mines, Spain

1. Introduction

Plants are the first compartment of the terrestrial food chain. Due to their capacity to accumulate potentially toxic trace elements, they can represent a threat to animals and humans that consume them (Intawongse and Dean, 2006; Liu et al., 2006).

The risk that trace elements pose to the environment and human health is a function of their speciation in soils and subsequent accumulation and partitioning within plants (Kabata-Pendias, 2004). The solubility of trace elements varies widely because many factors influence their concentration in the soil solution: edaphic characteristics (pH, texture and organic matter content), climatic conditions, and agronomic

47 management (Alloway, 1995, Chojnacka et al., 2005; Tokalioğlu and Kartal 2006). The
48 rate of metal translocation from the soil to edible and harvested parts of cultivated plants
49 depends, in addition, on vegetation type and metal involved, besides the soil and
50 climatic factors (Alloway, 1995; McLaughlin et al., 1999).

51 Chaney (1980) introduced the concept of the 'soil-plant barrier' and classified
52 trace elements in four groups with respect to their potential for food chain transfer:
53 Group 1 (Ag, Cr, Sn, Ti, Y and Zr) with low risk to human health because they are not
54 usually taken up by plants due to their low solubility in soil. Group 2 (As, Hg and Pb)
55 which are strongly sorbed by soil colloids, or may be immobilized in plant roots with
56 very limited transfer to edible shoot tissues, and therefore pose marginal risks. Group 3
57 (B, Cu, Mn, Mo, Ni and Zn) are phytotoxic at concentrations that pose little risk,
58 although 'the soil-plant barrier' protects the food chain from these elements. Group 4
59 consists of Cd, Co, Mo and Se, which pose human or animal health risks at plant tissue
60 concentrations that are not phytotoxic.

61 Soil pollution with trace elements, mainly those from Groups 2 and 3 described
62 above, represents one of the most prominent environmental hazards from abandoned
63 mine sites in the Iberian Pyrite Belt (Fernández-Caliani et al. 2009a, b; Fernández-
64 Caliani and Barba-Brioso, 2010). Past mining and ore processing activities resulted in
65 deforestation and destruction of the natural vegetation, transforming soils into marginal
66 lands unable to sustain commercial agriculture. However, traditional small-scale
67 agriculture has persisted on limited areas of arable land adjacent to the mining villages
68 in this region.

69 The goals of the study reported here were to: 1) determine total concentrations of trace
70 elements in different parts of fruit and vegetables, and in the soil in which they grew,
71 focusing on their edible parts; 2) assess the mobile and potentially-mobile fractions of

the soil trace element pools and the soil-plant transfer factors for the crops grown here; and 3) evaluate the long-term sustainability of the traditional soil management practices used in this region for marginal or soils of low fertility in relation to soil-plant transfer of inorganic pollutants.

2. Site description

The Tharsis Mines (UTM coordinates: X= 666,746 and Y= 4,162,779) are located in one of the oldest and best-known mining districts in the Iberian Pyrite Belt (South-West Spain), with a lengthy history of exploitation that dates back to pre-Roman times (Checkland, 1967). The most intensive period of mining operations occurred between the end of the 19th century and the middle of the 20th century, when pyrite was the main raw material used for sulphuric acid manufacture by the European chemical industry. Past mining and smelting activities were carried out without concern or even awareness of their negative environmental impact, resulting a present-day landscape of large opencast mines, waste rock piles and tailings dams that encompass an area of about 350 ha (Figure 1a).

During mining and after closure, pollutants have been transferred from the mine wastes to nearby soils by acid mine drainage and/or atmospheric deposition of wind-blown dust. Soils and vegetation show elevated trace element concentrations up to 2-3 km away from the mining area (Chopin and Alloway, 2007a,b). There are also a number of small holdings, none of which exceeds one hectare in extent, located in the immediate vicinity of the mine waste dumps, all at risk of contamination with metals.

Five agricultural plots, close to the sulfidic waste dumps of the “Filón Norte” open pit (Figure 1 b, c) were selected for this study. The alluvial soils of these plots are devoted to traditional horticulture, despite the fact that they are occasionally flooded by

acid waters emanating from nearby waste dumps and surface mine workings. To correct soil acidity, farmers routinely amend soils with lime, together with regular additions of animal manure. These practices have taken place for at least 25 years in the investigated plots, a fact established by interviews with each plot owner. The main crops cultivated by the smallholders are vegetables, typically lettuce (*Lactuca sativa* L.), chard (*Beta vulgaris* (L.) var. *cicla* K. Koch), onion (*Allium fistulosum* L.) and potato (*Solanum tuberosum* L.). Some plots also contain mature Lemon trees (*Citrus limon* L. Brum).

3. Methodology

3.1 Materials and methods

A suite of vegetable samples, comprising leaf, bulb, tuber and fruit crops, along with their associated soils were randomly collected from each plot in April 2008 at the indicated stage of maturity (Table 1).

Composite soil samples were taken to a depth of 20 cm (Ap horizon) from each plot where sampled vegetables were growing. These were transported to the laboratory in polyethylene bags, air dried, disaggregated with a wooden roller, passed through a 2 mm stainless steel sieve, and homogenized prior to analysis. The particle-size distribution was determined by a combination of sieving and laser diffraction (Malvern MasterSizer instrument) methods. The pH, Eh and electrical conductivity values were measured with calibrated glass electrodes in a 1:2.5 (w/v) soil to water suspension. The content of total organic matter was determined by oxidation with potassium dichromate in a strong acid medium (Walkley-Black method), as described by Pansu and Gautheyrou (2006), and the carbonate content was measured by the Bernard calcimetry method.

Soil mineralogy was investigated in both bulk samples (<2 mm) and clay-size

122 fractions (<2 μm) by powder X-ray diffraction (XRD) on a Bruker-AXS D8-Advance
123 diffractometer, using monochromatic CuKα radiation at 40 kV and 30 mA. The fine
124 fraction was separated by sedimentation and analyzed in oriented aggregates of air-
125 dried, ethylene glycol-treated and thermal-treated samples for clay mineral
126 identification. Selected soil samples were examined by scanning electron microscopy
127 using a JEOL JSM-5410 instrument coupled with an energy dispersive X-ray
128 spectrometer (SEM-EDS).

129 Total concentrations of potentially toxic trace elements (As, Cu, Pb and Zn) in
130 soil samples were determined by inductively coupled plasma-optical emission
131 spectrometry (ICP-OES), (Jobin Yvon ULTIMA 2), after 4-acid (HF-$HClO_4$-HNO_3-
132 HCl) digestion of 0.1 g soil sample oven dried for 24 hours at 110 °C. Quality control
133 included the use of a method reagent blank and several certified reference materials
134 (SARM-1 and SARM-4 for soil analysis) to check accuracy and precision of the
135 analytical data (relative standard deviation below 10%).

136 In order to determine the most labile metal pools, an aliquot of each soil sample
137 (2 g) was subjected to single extractions by shaking for one hour with deionised water, a
138 mild neutral salt solution (0.01 M $CaCl_2$) or a complexing agent (0.05 M EDTA at pH
139 7) at a soil:solution ratio of 1:10 (w/v) (e.g. Houba et al. 1996; Ure et al., 1996). The
140 first two soil extract solutions were analyzed after centrifugation (for 10 min at 4500
141 rpm) by inductively coupled plasma mass spectrometry (ICP-MS), using a Hewlett
142 Packard 4500 instrument with detection limits of 0.01 μgL^{-1}, whilst EDTA-extractable
143 metals were determined by ICP-OES. All trace element concentrations were reported on
144 an oven-dry basis.

145 All plant samples (leaves, roots, bulbs, peel and seeds) were washed (for 10 s
146 approximately) with a solution of phosphate-free detergent, then with a 0.1 N HCl

147 solution and finally with distilled water. Plant material was oven-dried at 70ºC, ground
148 and passed through a 500 µm stainless steel sieve. A 0.5 g aliquot was digested by wet
149 oxidation with concentrated HNO_3 under pressure in a microwave digester (Jones and
150 Case, 1990). Three consecutive steps (5 min. each) of power (250 W, 450 W and 600
151 W) were applied, and then these extracts were diluted to 50 ml volume with deoinised
152 water of 18 mΩ quality. The analysis of trace metals in the digests was performed by
153 ICP-MS. The accuracy and precision of the analytical method were assessed by routine
154 analyses of the reference sample CRM-279 (Sea lettuce) and CS DC73350 (poplar
155 leaves). Recovery rates for reference plant samples were between 90 and 110%.
156
157 ***3.2 Treatment of analytical data***
158 Quantitative assessment of overall soil pollution was based on the pollution load
159 index (PLI), as defined by Tomlinson et al., (1980), taking into consideration the
160 concentration factor (CF), which is the ratio between each trace element in the soil and
161 its background value. The PLI of each soil sample was calculated by deriving the *n*-th
162 root of the *n* factors ($CF_1xCF_2xCF_3x...CFn$). Thus, values of PLI close to one indicate
163 heavy metal loads near the background level, while values >1 indicate soil pollution
164 (Cabrera et al., 1999).
165 In order to find out what proportion of the total soil metal concentration was
166 available and transferred to different organs of the vegetables grown by the
167 smallholders, the transfer coefficient (TC) was calculated. This is defined as the ratio of
168 metal concentration in the plant, [M]plant, to the total metal concentration in the soil,
169 [M]soil (Adriano, 2001).
170 TC = [M]plant / [M] soil

171 The data was statistically analysed using StatSoft Statistica 7.0 to recognize
172 variables trends and groupings. Kolmogorov-Smirnov and Shapiro-Wilk's normality
173 tests were carried out for all variables, refusing the normal distribution for almost all of
174 them. Because the variables required a non-parametric analyses, a Spearman correlation
175 matrix (significance level $p<0.01$) was obtained, correlating total trace element contents
176 in soils with those measured in soil extracts and plants.
177
178 **4. Results and discussion**
179 ***4.1 Soil constituents and properties***
180 The upper part of the soil profile shows a well-developed organic horizon with
181 granular structure and had similar edaphic properties in all the sampled soils (Table 2).
182 The soil is brown (10YR 5/3, 10YR 6/3 dry) in colour and has a silty loam texture with
183 <10% of clay-sized particles. Some soil samples contain significant amounts of coarse-
184 grained components (greater than 2 mm), consisting of sub-angular lithic fragments of
185 heterogeneous waste rocks and slag residues.
186 The soil had an average pH value of 7.4, and electrical conductivity ranged
187 between 0.15 and 0.95 mS cm^{-1}, indicating a low salinity level in the soil solution. The
188 soil appears to be well drained and aerated spanning a narrow range of positive Eh
189 values (457-505 mV) that reflect moderately oxidizing conditions.
190 The soil has a high content of total organic matter (8.1-14.9%) and carbonates
191 (up to 14%) resulting from the application of organic amendments and lime to improve
192 soil fertility and to prevent soil acidity.
193 Soil minerals, identified by XRD, were composed of phyllosilicates (50-60%),
194 quartz (30-40%), feldspars (5-10%), calcite (<5%) and dolomite (<5%). The clay
195 mineral assemblage was dominated by illite and kaolinite, with minor vermiculite

196 and/or poorly defined mixed-layer phases. In addition, SEM-EDS analysis revealed the
197 occurrence of amorphous or poorly crystalline Fe oxyhydroxides and a number of
198 accessory minerals, such as baryte, apatite and monazite.
199
200 ***4.2 Total concentrations of trace elements in soil***
201 The sampled soils contained high levels of As, Cu, Pb and Zn (Table 3),
202 although total concentrations varied, depending on the location of the sampling plot
203 (Figure 1). The highest concentrations of trace elements (up to 621 mg kg^{-1} As, 752 mg
204 kg^{-1} Cu, 2395 mg kg^{-1} Pb, and 593 mg kg^{-1} Zn) were found in plots 4 and 5, located in
205 the immediate vicinity of the mine wastes. Similar total soil element concentrations
206 have been reported for cultivated soils adjacent to other abandoned mine sites in the
207 Iberian Pyrite Belt (López et al., 2008; Fernández-Caliani et al. 2009a).
208 The total concentrations of As, Cu, Pb and Zn in these soils are between one and
209 two orders of magnitude above both the regional geochemical baseline (Galán et al.
210 2008) and normal levels found in Spanish agricultural soils (López-Arias and Grau-
211 Corbí, 2005). Furthermore, these values greatly exceed the maximum allowable
212 concentrations for agricultural soils established by the Regional Government of
213 Andalusia (Aguilar et al., 1999). This indicates potential health risks associated with
214 consuming edible crops grown in these soils.
215 The Concentration Factor, CF, defined as the ratio between each trace element in
216 the soil sample and its background value (50^{th} percentile), was particularly elevated for
217 As (up to 24.8), Cu (up to 23.5), and Pb (up to 63.0), indicating soil pollution. The
218 lowest CF values were found for Zn, although the ratio was higher than 1 for all
219 samples. Pollution load indices (PLI) at each plot are shown in Table 3. The PLI values

220 varied between 9.4 (plot 1) and 22.8 (plot 5), reflecting the high pollution loads of As,
221 Cu, Pb and Zn, especially in plots near the mine wastes.
222
223 ***4.3 Trace element concentrations extracted with water, $CaCl_2$ and EDTA***
224 Water, $CaCl_2$ and EDTA remove trace elements from different compartments
225 within the overall soil matrix. The water-soluble fraction and the fraction assessed by
226 $CaCl_2$-extraction are considered to simulate the proportion of the total soil metal pool
227 that may be available for uptake by plants and play a key role in many transfer pathways
228 (Gupta et al. 1996; Houba et al. 1996). The EDTA-extractable fraction is composed of
229 those ions present in the soil solution, as well as those that are loosely bound to sites in
230 the solid phase of the soil and potentially able to move into the plant root system
231 (Madejón et al., 2009). In some cases, EDTA-extractable metal concentrations have
232 been reported to be closely correlated with metal concentrations in plants (e.g.
233 Sahuquillo et al., 2003), although methodology for assessing the bioavailability of
234 metals in soil is a controversial issue (Menzies et al., 2007).
235 The mean water-soluble and $CaCl_2$-extractable concentrations of As, Cu, Pb and
236 Zn were found to be less than 1 mg kg^{-1} in all the agricultural plots (Table 3), whereas
237 the EDTA-extracted mean concentrations were higher, and varied widely depending on
238 the trace element involved (2.9-7.2 mg kg^{-1} for As, 22.3-32.6 mg kg^{-1} for Cu, 46.4-95.8
239 mg kg^{-1} for Pb, and 17.8-20.3 mg kg^{-1} for Zn). Accordingly, the mobile and very active
240 metal fraction was practically negligible (lower than 0.22%), and the EDTA-extractable
241 fraction was below 10% (Figure 2), indicating a limited potential mobility of all
242 elements despite their high total concentrations in soil. No significant correlation was
243 observed between the extractable concentrations and the total concentrations in soil for
244 all the investigated elements, suggesting that the pollution load did not have a

noticeable effect on the proportion of water soluble, exchangeable and complexed fractions. These results are in good agreement with previous studies on soils from this area (Barba-Brioso et al., 2007; Chopin and Alloway, 2007a,b).

In general, trace elements showed the following order of relative abundance in the mobile fraction: As > Cu > Zn > Pb. Therefore, As seems to be the most easily extractable trace element in soil. This can be explained by the fact that, under circumneutral pH conditions, As mobility can be increased in soils (Hartley et al., 2004). Arsenic usually forms water-soluble oxyanion species which are repelled by the negatively-charged surfaces of soil particles, thus preventing the adsorption of As oxyanions. A further finding supports our assumption: As concentration up to 138 $\mu g\ L^{-1}$ compared to much lower to Cu and Zn concentrations ($< 5\ \mu g\ L^{-1}$) were measured in groundwater from a nearby well (unpublished data); the guideline value for As irrigation water is 0.1 $mg\ L^{-1}$ (FAO, 1985). On the other hand, the low extractability of Pb with water and $CaCl_2$ indicated that this trace element was more strongly bound to constituents of the soil than As, Zn, and Cu.

Differences between elemental concentrations removed by the 3 extractants show that each provides different information on the metal status of the tested soils. As EDTA is a chelating agent that extracts elements by forming complexes with cations, it can access trace elements associated with stable binding sites within the soil matrix. The higher extractability of trace elements with EDTA (Table 3) compared with water and $CaCl_2$ extraction could be due to EDTA removing trace elements bound to organic matter (soil OM contents were between 8 and 15%, Table 2).

Speciation of trace elements in soils is mainly related to pH (McLaughlin et al., 2000). Although there were no correlation patterns between pH and extractable trace elements, the low extractability of Cu and Zn compared to their total concentrations

could also be related to the neutral pH of the soil (Madejón et al., 2009). Correlations between pH and both water and $CaCl_2$ extraction were significant ($P<0.01$) for As ($r_{H_2O}= 0.59$ and $r_{CaCl_2}= 0.62$), Cu ($r_{H_2O}= 0.49$ and $r_{CaCl_2}= 0.52$) and Pb ($r_{H_2O}= 0.60$ and $r_{CaCl_2}= 0.82$). Significant correlations between pH and EDTA extraction were only found for Zn ($r= 0.34$).

4.4 Trace element content of plants

The elements that most commonly produce concerns about food safety are Cd, Hg, Pb, As and Se (Reilly, 1991). In addition, some micronutrients (e.g. Cu, Cr, Ni, Zn) may be toxic to both plants and animals when present at high concentrations (McLaughlin et al., 1999). Of the trace elements investigated here, As is considered to pose the major risk for human food-chain contamination (Kabata-Pendias and Pendias, 1999, 2001).

Trace element content of onion bulb differed; this could be related depending on the stage of development when bulbs were sampled. In young onions bulbs, As concentration reached values up to 23.5 mg kg^{-1} (above the statutory limits, Table 4). When the onion ripened and increased its biomass, this concentration decreased, analysis showing values below the statutory limit. This could be related to a 'dilution effect' of elements due to biomass increase with no concomitant increase in trace element uptake; this has been previously considered in the literature (e.g. Jarrel and Beverly 1981). Leafy vegetables such lettuce and chard are classified as crops with a high potential for trace element transfer from soil to the edible foliage (Pillay and Jonnalagadda, 2007), however Juhasz et al. (2008) found that such vegetables were poor As accumulators. In the case of the lettuces and chard sampled here, As contents in the edible leaves were within normal and statutory levels for vegetables. It is interesting to

295 note that the highest As concentrations were found in roots and outer leaves of lettuce
296 (the most external dark green leaves), both non-edible parts of this vegetable (Figure 4).
297 Plants showed similar patterns of Pb uptake and partitioning as found for As;
298 maximum contents in roots, up to 51.8 mg kg^{-1} in onions (Table 4) and 13 mg kg^{-1} in
299 lettuce (Figure 4). This is in agreement with other observations on Pb uptake and
300 distribution in plants (Adriano, 2001). In these soils, the soil–plant barrier may act to
301 protect the human food chain against Pb toxicity (Chaney, 1989). Similar results for As
302 and Pb uptake in onion and lettuce were reported by Lim et al. (2008). The effect of
303 biomass increase in onions was also evident, bulbs of young onions showed Pb contents
304 up to 8 mg kg^{-1} in the edible part, but in ripe onions Pb content decreased to values
305 below statutory levels (Table 4). This reflects the nature of bulb development, with
306 biomass added as a result of carbohydrate transport from leaves. The Pb content of
307 lettuce and chard foliage was also below statutory limits. There were also no age-
308 dependant differences in Pb distribution in mature lettuce heads: the older, outer leaves
309 had very similar Pb content to their less mature counterparts in the centre of the head
310 (Figure 4).
311 The concentrations of As and Pb detected in whole potatoes, peel and tuber,
312 were negligible (0.1 mg kg^{-1}). There was no evidence of As contamination in potato
313 tubers, which is in agreement with other findings (Dahal et al. 2008).
314 Copper and Zn have important physiological roles as micronutrients in plants,
315 however excess concentrations in edible plant parts may pose a risk to both humans and
316 animals. Maximum values for Cu and Zn were found in onion roots (up to 80 mg kg^{-1}
317 Cu and 135 mg kg^{-1} Zn, Table 4), although that was not the case for lettuce roots. In
318 case of Cu, concentrations in onion leaves (maximum of 30 mg kg^{-1}, above normal
319 levels in plants) were higher than in bulbs in contrast to data for Zn. The dilution effect

320 of trace elements (bulbs of mature *vs* young onions) was also observed for Cu and Zn.
321 In general, concentrations in onions were above normal concentrations found in this
322 plant according to Mohamed et al. 2003 (2.81 mg kg^{-1} for Cu and 17.6 mg kg^{-1} for Zn)
323 and Kabata-Pendias and Pendias 1999, 2001 (Table 4). Likewise the contents of Cu and
324 Zn in lettuce and chard were within the normal range reported in plants, although for Cu
325 these contents were higher than contents in the same species from non-polluted sites
326 (lettuce 3.81 mg kg^{-1} Cu and 81.5 mg kg^{-1} Zn and chard 5.49 mg kg^{-1} Cu and 150 mg
327 kg^{-1} Zn, Pillay and Jonnalagadda, 2007). The maximum concentrations of Cu and Zn in
328 lettuce were detected in the inner leaves (Figure 4), so the distribution patterns of both
329 micronutrients were different from those found for As and Pb.
330 The relatively high concentrations of Cu in onion leaves, lettuce and chard could
331 have been influenced by foliar absorption of Cu-based agrochemicals, which are applied
332 by the local farmers. Plants growing on Cu-polluted sites tend to accumulate increased
333 amounts of this metal, especially near industrial areas and in soils treated with Cu-
334 bearing pesticides (Kabata-Pendias and Mukherjee, 2007).
335 Elemental concentrations in different organs of lemon trees are shown in Figure
336 5. Arsenic and Pb reached the highest contents in leaves (although within the normal
337 range in plants) whereas concentrations of these potentially toxic elements in different
338 parts of the fruit were very low, especially in seed (0.1 mg kg^{-1}). Both trace elements in
339 lemon leaves and fruits followed the same pattern found in other trees growing on
340 polluted soils: high content in leaves and much lower in fruits and seeds (Madejón et al.,
341 2006). Ernst et al. (1992) reported that plants do not totally exclude trace elements (with
342 no essential function in the plant) from their reproductive organs although the content in
343 fruits and seed is usually very low. On the other hand, Cu and Zn showed a similar

distribution pattern, with high concentrations in leaves and in seeds when compared to As and Pb.

Finally, the concentrations of As and Pb detected in whole potatoes, peel and tuber, were negligible (0.1 mg kg^{-1}), whereas the concentrations of Cu in tubers (up to 12.0 mg kg^{-1}) and Zn (up to 28.8 mg kg^{-1}) were greater than those compiled by Kabata-Pendias and Pendias (1999, 2001) as possible background values.

4.5 Trace element correlations between soil and plants and soil-plant transfer coefficients

Significant correlations between soils and plants (taking together all species and plant parts) were found for As with water and $CaCl_2$ extraction (r_{H_2O}= 0.45 and r_{CaCl_2}= 0.46). Correlation coefficients for each species could be only calculated for young onions, lettuce and chard. There were significant correlations between As in lettuce leaves and EDTA extractable As (r= 0.86) and chard leaves and pH (r= -0.87). For Pb, significant negative correlations were found between lettuce and chard and total soil Pb content; this may be indicative of a non-soil pollution source (wind-blown dust). Significant soil-plant correlations for Cu were found for lettuce and chard and for total, EDTA and $CaCl_2$ extraction concentrations, but these are less robust due to the low number of samples.

The soil-plant transfer coefficients were calculated for As, Cu, Pb and Zn (Table 5). The transfer factors may depend not only on plant species, but also on the element concentration and bioavailability in soil (Huang et al., 2006). The values calculated were, in general, very low, especially in the case of As and Pb, and in the different tissues of lemon and potato that were analyzed. It has been observed that transfer factors tended to decrease with increasing soil concentrations (Alan et al., 2003). In the case of

onions, the high As TC in roots, (TC= 3.03) coupled with the greatly reduced transfer to aerial parts (TC= 0.03) and bulb (TC= 0.001) would indicate that the As accumulated in root tissues. In case of Cu and Zn, TC were always low, with maximum values found in onion roots (TC= 0.15 for Cu and 0.18 for Zn). Similar results were found for other plants growing in multi-element polluted soils by Madejón et al. (2007). The present results imply that there is a low transfer of pollutants from these soils to primary producers.

5. Conclusions

There are several conclusions that can be drawn from this study:

First: There is limited soil-plant transfer of potentially hazardous trace elements (As, Cu, Pb, Zn) to selected vegetables and fruit cultivated on a mine-polluted soil. One reason may be the current management practices employed on the agricultural small holdings under investigation such as regular inputs of organic matter and lime to maintain soil pH close to neutrality.

Second: The vegetables investigated are typical of those grown in this region, and no edible part showed element accumulation that could be considered as a significant risk to human health, based on statutory limits for food crops. The vegetables showed different patterns of trace element accumulation: highest concentrations in non-edible parts of onions and lowest concentrations in potatoes tubers.

Third: The data from this survey is a clear illustration of the use of simple, routine agronomic procedures as a means of a) cultivating crops on potentially phytotoxic soils and b) reducing the concentrations of potentially toxic elements (As, Pb) in their edible tissues. Routine application of a combination of livestock manure and agricultural lime has created a soil environment where the labile pools of As and Pb are very low, in

contrast to the very elevated total content of these elements in the soil. In addition, this treatment has regulated plant uptake of both Cu and Zn, reducing potential phytotoxicity whilst still providing a source of trace concentrations of both micronutrients to maintain normal growth. The *ad hoc* treatments applied by the smallholders appear to have successfully contributed to the safe use of the polluted soils where it can sustain crop production over an extended period of time. There are clear lessons for future development of field scale remediation of soils with mixed metal/metalloid pollution from the successful and sustainable outcome of the 'in situ' treatments applied to these highly polluted soils by the smallholders who use traditional practices to farm these sites. However it is important to consider that the success obtained in this case cannot be generally extended to other situations where soil and climate conditions, as well as type of crop species, are different.

Chard (plot 2, n=3)	Leaves	1.07 (0.77-1.30)	18.4 (16.0-19.9)	1.50 (1.2-1.76)	79.8 (54.2-110)
Potato (n=5)	Peel	0.1	11.5 (8.9-12.6)	0.1	21.1 (19.2-24.0)
	Tuber	0.1	10.3 (8.2-12.0)	0.1	25.0 (20.8-28.8)
*Potato tubers**		-	*3.0-6.6*	*0.5*	*10-26*
Normal levels in vegetables**		0.0001-0.46	0.04-2.4	0.0004-0.8	0.5-118
Statutory limits***		1.00	-	1.00	

* Possible background values compiled by Kabata-Pendias and Mukherjee (2007); **Szefer and Nriagu, (2007); *** Davis and White (1981)

Table 5. Transfer coefficients (TC) for As, Cu, Pb and Zn at the different organs of the studied vegetables.

Vegetable	**organ**	**As**	**Cu**	**Pb**	**Zn**
Ripe onion	Leaves (n=6)	0.034	0.034	0.001	0.03
	Bulbs (n=6)	0.001	0.011	0.0004	0.05
	Roots (n=3)	3.03	0.150	0.052	0.18
Young onion	Leaves (n=7)	0.020	0.03	0.002	0.04
	Bulbs (n=7)	0.017	0.02	0.001	0.11
Lettuce	Leaves (n=6)	0.003	0.03	0.0005	0.13
Chard	Leaves (n=6)	0.003	0.04	0.001	0.14
Lemon	Leaves (n=3)	0.003	0.015	0.0007	0.03
	Pulp (n=3)	0.0002	0.010	0.0001	0.02
	Peel (n=3)	0.0002	0.005	0.0002	0.01
	Seed (n=3)	0.0002	0.014	0.00005	0.04
Potato	Peel (n=5)	0.0002	0.015	0.00004	0.035
	Tuber (n=5)	0.0002	0.014	0.00004	0.04
